## Abstract

Studies of several mammalian species confirm that formant frequencies (vocal tract resonances) predict height and weight better than does fundamental frequency ( $F_0$ , perceived as pitch) in same-sex adults due to differential anatomical constraints. However, our recent meta-analysis [Pisanski et al. (2014) *Animal Behaviour*, 95, 85-99] indicated that formants and  $F_0$  could explain no more than 10% and 2% of the variance in human height, respectively, controlling for sex and age. Here, we examined whether other voice parameters, many which are affected by sex hormones, can indicate additional variance in human body size or shape, and whether these relationships differ between the sexes. Using a cross-cultural sample of 700 men and women, we examined relationships among 19 voice parameters (min-max  $F_0$ , mean  $F_0$ ,  $F_0$  variability, formant-based vocal tract length estimates, shimmer, jitter, harmonics-to-noise ratio) and 8 indices of body size or shape (height, weight, body-mass-index BMI, hip-, waist- and chest-circumferences, waist-to-hip ratio WHR, chest-to-hip ratio CHR). Our results confirm that formant measures explain the most variance in men's and women's heights and weights, whereas shimmer, jitter, and HNR do not indicate height, weight, or BMI in either sex. In contrast, these perturbation and noise parameters, in addition to  $F_0$  range and variability, explained more variance in body shape than did formants or mean  $F_0$ , particularly among men. Shimmer or jitter explained the most variance in men's hip circumferences (12%) and CHRs (6%) whereas HNR and formants explained the most variance in women's WHRs (11%), and significantly more than in men's WHRs. Our study represents the most comprehensive analysis of vocal indicators of human body size to date and offers a foundation for future research examining the hormonal mechanisms of voice production in humans and perceptual playback experiments.

**Keywords:** voice; acoustic communication; sexual selection; formant; fundamental frequency; jitter; shimmer; body size; waist-to-hip ratio; chest-to-hip ratio

24 Many animals use vocalizations to communicate in social contexts. Vocalizations may  
25 communicate an animal's motivation state (Morton, 1977) but can also function as indexical cues to  
26 identity, sex, and various physical traits (Ghazanfar & Rendall, 2008; Owren, 2011). Bioacoustic  
27 analyses suggest that the vocalizations of mammals contain reliable and perpetually salient information  
28 about a vocalizer's body size and mass (Ey, Pfefferle, & Fischer, 2007; Pisanski, Fraccaro, Tigie,  
29 O'Connor, Röder, et al., 2014a; Taylor & Reby, 2010), and playback experiments suggest that both  
30 human and non-human listeners may use vocalizations to gauge the body size of conspecifics (e.g.,  
31 humans, *Homo sapiens*: Charlton, Taylor, & Reby, 2013; Pisanski, Fraccaro, Tigie, O'Connor, &  
32 Feinberg, 2014b; Rendall, Vokey, & Nemeth, 2007; Smith & Patterson, 2005; red deer, *Cervus*  
33 *elaphus*: Charlton, Reby, & McComb, 2007; koalas, *Phascolarctos cinereus*: Charlton, Whisson, &  
34 Reby, 2013; rhesus macques, *Macaca mulatta*: Fitch & Fritz, 2006; dogs, *Canis lupus familiaris*:  
35 Taylor, Reby, & McComb, 2010).

## 36 **Vocal Indicators of Body Size**

37 Following the source-filter theory of speech production (Fant, 1960), researchers attempting to  
38 uncover which voice parameters may reliably indicate body size in humans and other mammals have  
39 focused on two largely independent features of the voice: mean fundamental frequency ( $F_0$ ,  
40 produced by vocal fold vibration and perceived as voice pitch) and formant frequencies (produced by  
41 filtering of the supralaryngeal vocal tract; Titze, 1994). Among humans, our recent meta-analysis  
42 showed that formants predict height and weight more reliably than does  $F_0$  when sex and age are  
43 controlled (Pisanski et al., 2014a). This finding supports the prediction that mammalian formants are  
44 more anatomically constrained than is  $F_0$  (Fitch, 1994, 2000) and corroborates findings from several  
45 other mammalian species (reviewed in Kreiman & Sidtis, 2011). However, the meta-analysis also  
46 highlighted that formants could explain no more than 10% of the variance in men's heights whereas  
47 mean  $F_0$  explained less than 2%. Formants accounted for even less of the variance in women's heights

48 (6%) whereas mean  $F0$  was not significantly correlated with height among women (Pisanski et al.,  
49 2014a). Due to the limited number of studies investigating other kinds of voice-body relationships, the  
50 meta-analysis did not test whether vocal features other than mean  $F0$  or formants could explain  
51 additional variance in human body size, and did not examine relationships between the voice and body  
52 shape, such as circumference parameters.

### 53 **Fundamental Frequency Range and Variability**

54 A growing literature suggests that several voice parameters, in addition to formants and mean  
55  $F0$ , may indicate body size and shape in one sex or the other. These voice parameters include non-  
56 mean-based measures of fundamental frequency such as minimum  $F0$ , maximum  $F0$ , and  $F0$   
57 variability (the standard deviation of  $F0$ ,  $F0\ sd$ ) that are sexually dimorphic (Puts, Apicella, &  
58 Cardenas, 2012). These source measures indicate the upper and lower range of an individual's voice  
59 pitch and the degree to which voice pitch deviates from baseline across an utterance. The standard  
60 deviation of men's  $F0$  appears to be a particularly reliable indicator of status, correlating negatively  
61 with self-reported dominance, reproductive success, and testosterone levels (Hodges-Simeon, Gaulin,  
62 & Puts, 2010, 2011). In a cross-cultural study, Puts and colleagues (2012) found that  $F0\ sd$  predicted  
63 self-reported physical aggression in American men, and was marginally negatively related to arm  
64 strength among American but not Hadza men. In that study, however, formants reliably predicted  
65 height in both samples of men, whereas  $F0\ sd$  did not.

### 66 **Vocal Perturbation and Noise**

67 Vocal frequency perturbation (jitter), amplitude perturbation (shimmer), and noise (harmonics-  
68 to-noise ratio) parameters may also correlate with body size or shape as they relate to the mass and  
69 oscillating properties of the vocal folds. Jitter and shimmer measure the mean deviation in voice pitch  
70 or amplitude between adjacent cycles, whereas harmonics-to-noise ratio (HNR) measures the relative

71 degree of periodicity to aperiodicity in the voice. A relatively high degree of jitter or shimmer or a low  
72 HNR can indicate irregular vocal fold vibration, often caused by laryngeal asymmetry in mass or  
73 tension, which can result in vocal breathiness and hoarseness (Buder, 2000). Traditionally these  
74 measures have been used by clinicians to assess voice quality in pathological voices (Maryn, Roy, De  
75 Bodt, Van Cauwenberge & Corthals, 2009), however several researchers have criticized the validity of  
76 jitter and shimmer as reliable indices of voice quality (Hillenbrand, 1987; Maryn et al., 2009; Kreiman  
77 & Gerratt, 2005).

78 Linders, Massa, Boersma and Dejonckere (1995) suggested that jitter and body size may be  
79 negatively related to the extent that larger, more massive vocal folds may result in a mechanical  
80 dampening of vocal fold oscillation, producing a steadier voice pitch (see also Lieberman 1963; Titze,  
81 1988). However, vocal fold mass is more closely related to sex hormone levels than to height, where  
82 for example pubertal increases in testosterone masculinise and enlarge the vocal folds causing  $F_0$  to  
83 drop (Hollien, Green, & Massey, 1994; Prelevic, 2013). Indeed, researchers have long proposed that  
84 sex hormones may influence voice perturbation and noise parameters, either by affecting the mass of  
85 the vocal folds, or the motor and sensory processes involved in laryngeal control (e.g., Higgins &  
86 Saxman, 1989; Silverman & Zimmer, 1978; for more recent work see Gugatschka, Kiesler,  
87 Obermayer-Pietsch, Schoekler, Schmid, Groselj-Strele, & Friedrich, 2010; Prelevic, 2013). It follows  
88 that jitter, shimmer and HNR may relate to body size and in particular body shape via the shared  
89 influence of sex hormones on these vocal properties and on the development and distribution of fat and  
90 muscle on the body.

91 Relationships between perturbation or noise parameters and the human body have been  
92 examined in only a small number of studies with mixed results. González (2007) found that jitter  
93 correlated positively with women's body mass, such that heavier women showed more irregularities in  
94 their voice pitch, whereas shimmer and HNR were relatively poor indicator's of women's, and even

95 less so men's, heights and weights. In contrast, Linders et al. (1995) reported a negative correlation  
96 between jitter and height in prepubescent girls and boys independent of gender, suggesting that before  
97 puberty, shorter children show more irregularities in their voice pitch than do taller children. Finally,  
98 Hamdan et al. (2012) failed to find relationships between jitter or HNR and body size, but reported  
99 weak positive relationships between shimmer and trunk fat or muscle mass in men. The largest same-  
100 sex sample among these studies included only 81 individuals (González, 2007), which may be too few  
101 to detect various voice-body relationships.

## 102 **Vocal Indicators of Body Shape**

103 There is some evidence that information about body *shape*, not only height and weight, may be  
104 present in the human voice. The principle mechanism linking voice to body shape may be hormonal  
105 (Hughes & Gallup, 2008). In addition to affecting voice  $F_0$  and formants, and possibly also  
106 perturbation parameters (Abitbol, Abitbol, & Abitbol, 1999; Dabbs & Mallinger, 1999; Lieberman,  
107 McCarthy, Hiiemae, & Palmer, 2001), estrogens and androgens affect the circumferences of the waist,  
108 hips, and chest and the ratios among them (waist-to-hip ratio, WHR and chest-to-hip ratio, CHR), as  
109 well as an individual's body-mass-index or BMI (Blouin, Boivin, & Tchernof, 2008; Derby, Zilber,  
110 Brambilla, Morales, & McKinlay, 2006; Evans, Hoffmann, Kalkhoff, & Kissebah, 1983)<sup>1</sup>.

111 Similar to physical height, indices of body shape such as WHR and CHR can provide socially  
112 relevant information about an individual (Hughes & Gallup, 2008). For instance, body shape predicts a  
113 wide range of health-related factors in both sexes, controlling for body mass (Blouin et al., 2008;  
114 Larsson et al., 1984; Seidell, 2009). Among women, WHR and BMI are robust predictors of fecundity  
115 and correlate with ratings of women's physical attractiveness from photographs (Kaye, Folsom,

---

<sup>1</sup> These indices of body shape are sexually dimorphic and can vary independently of one another within the same individual. It is also important to note that the distribution of fat and muscle mass on the body that determines body shape is largely independent of the amount of fat and muscle on the body that determines body mass (Singh & Singh, 2011).

116 Prineas, Potter, & Gapstur, 1990; Singh, 1993; Zaadstra et al., 1993). Women with lower WHRs are  
117 also rated as having more attractive voices (Hughes, Dispenza, & Gallup, 2009), and listeners are able  
118 to gauge women's WHRs from their voices alone (Hughes, Harrison, & Gallup, 2009). Among men,  
119 CHR and height positively predict physical attractiveness and reproductive success (Pawlowski,  
120 Dunbar, & Lipowicz, 2000; Swami et al., 2007). Like body size, body shape influences mate  
121 preferences across a range of human cultures (Pisanski & Feinberg, 2013) and is likely to be important  
122 for both mate selection and intersexual competition.

123 Few studies have examined vocal indicators of body shape compared to body size, and again  
124 the results of this work are mixed. Early studies examined relationships between principal components  
125 of voice and body shape (i.e., factor scores) in small samples of men or women ( $n = 26-34$ ), making  
126 interpretation of results difficult. In these studies, Collins (2000) and Bruckert et al. (2006) failed to  
127 find relationships between voice and body shape components among men, whereas Collins and Missing  
128 (2003) reported that women with higher harmonics (integer multiples of  $F_0$ ) had lower scores on a  
129 body component comprised of BMI, weight, waist- and hip-circumference. Evans, Neave and Wakelin  
130 (2006) reported negative relationships between men's mean  $F_0$  and their shoulder- and chest-  
131 circumferences or shoulder-to-hip ratios, but no relationship between men's  $F_0$  and shoulder-to-waist  
132 or waist-to-hip ratios. More recently, in a sample of 109 women, Vukovic, Feinberg, DeBruine, Smith  
133 and Jones (2010) reported negative relationships between women's mean  $F_0$ 's and their BMIs and hip-  
134 circumferences, but not waist circumferences or WHRs.

### 135 **Key Research Questions**

136 The present study addresses the key open research questions: (1) Do voice parameters other  
137 than formants and mean  $F_0$  explain additional variance in men's and women's heights and weights  
138 (i.e., body size)? (2) Does any voice parameter explain variance in the circumferences and

139 circumference ratios of the waist, hips, and chest (i.e., body shape)? (3) Do voice parameters explain  
140 more variance in the body size or shape of one sex than the other? To answer these questions we  
141 examined relationships among 19 voice parameters and 8 indices of body size or shape in a large cross-  
142 cultural sample of adult men and women. To our knowledge, our study is the first to examine  
143 relationships between body shape and any of the following vocal parameters: minimum  $F0$ , maximum  
144  $F0$ ,  $F0$  variability, jitter, shimmer and HNR. Although the voice-body relationships investigated in this  
145 study were chosen on the basis of the theoretical and empirical work reviewed above, the study is  
146 exploratory in nature. The principle aim of the study is to offer a comprehensive account of vocal  
147 correlates of body size and shape in humans that may help researchers to generate novel testable  
148 hypotheses concerning the mechanisms and functions of these relationships, and ultimately allow for a  
149 meta-analysis of less commonly studied voice-body relationships.

## 150 **Methods**

### 151 **Sample Characteristics**

152 Voice recordings and body measures derived from a total of 700 ( $N$ ) adults from Canada ( $n$ =  
153 118 women; 185 men), Scotland ( $n$ =235 women, 111 men) and Germany ( $n$ =85 women). Age data  
154 were available for the Canadian (men:  $18.7 \pm 1.5$ , women:  $19 \pm 2.3$ , range 17-30 years) and German  
155 samples ( $23.1 \pm 2.2$ , range 19-30 years). Voice recordings and body measures were initially collected  
156 for other research; as a result, age data were unavailable for the Scottish sample and only female  
157 participants were included in the German sample. All participants were students at local universities  
158 who provided written informed consent to participate in the study and all procedures were approved by  
159 the research ethics review board.

### 160 **Voice Recording**

161 Participants were recorded in a sound attenuated chamber using a professional condenser  
162 microphone with a cardioid pick-up pattern and at an approximate distance of 5–10 cm. All participants  
163 were recorded speaking five vowel sounds. For the Canadian and German samples the five vowels  
164 were /a/, /i/, /ε/, /o/, and /u/ (International Phonetic Alphabetic notation). For the UK sample the vowels  
165 were /eI/, /i/, /aI/, /o/, and /ju/.

## 166 **Voice Measurement and Analysis**

167 Voice measurements and analyses were performed in Praat (Boersma & Weenink, 2013). For  
168 each vocalizer we analyzed 19 voice parameters including minimum and maximum  $F0$ , mean  $F0$ , the  
169 standard deviation of  $F0$  ( $F0\ sd$ ), three perturbation or noise parameters (shimmer, jitter, and  
170 harmonics-to-noise ratio, HNR), the first to fourth formants ( $F1$ - $F4$ ), and several amalgamated  
171 formant-based parameters, henceforth termed vocal tract length (VTL) estimates, that included:  
172 Average Formant Frequency,  $F_n$  (Pisanski & Rendall, 2011); Formant Dispersion,  $D_f$  (Fitch, 1997),  
173 Formant Position,  $P_f$  (Puts et al., 2012); Formant Spacing and Apparent Vocal Tract Length derived  
174 from formant spacing,  $\Delta F$  and  $VTL(\Delta F)$  (Reby & McComb, 2003); Apparent Vocal Tract Length  
175 derived from mean formants,  $VTL(F_i)$  (adapted from Fitch, 1997; see also Titze, 1994); Geometric  
176 Mean Formant Frequency, MFF (Smith & Patterson, 2005); and factor scores from a confirmatory  
177 factor analysis, CFA (Turner, Walters, Monaghan, & Patterson, 2009). The algorithms used to compute  
178 VTL estimates are provided in Pisanski et al. (2014a). All mean voice measurements were taken from  
179 the steady-state portion of each of five isolated vowels per vocalizer, averaged within vocalizers, and  
180 then within sex to obtain mean values.

181 We measured all  $F0$  parameters using Praat's autocorrelation algorithm with a search range set  
182 to 65-300 Hz for men and 100-600 Hz for women and measured formants  $F1$ – $F4$  using Praat's Burg  
183 Linear Predictive Coding algorithm with the initial settings of maximum formant set to 5000 Hz for  
184 men and 5500 Hz for women. Formants were first overlaid on a spectrogram and formant number was

manually adjusted until the best visual fit of predicted onto observed formants was obtained (Boersma & Weenink, 2013; see Praat user manual, [www.praat.org](http://www.praat.org)). The fundamental frequency and formant measures we obtained (see Table 1) agree well with weighted population-level averages (Pisanski et al., 2014a). From the mean  $F1$ – $F4$  values we computed eight different VTL estimates ( $F_n$ ,  $D_f$ ,  $P_f$ ,  $\Delta F$ ,  $VTL(\Delta F)$ ,  $VTL(F_i)$ , MFF, and CFA; see Table 1 for descriptive statistics, and Pisanski et al. (2014a) for additional details and algorithms used to compute VTL estimates).

We measured one noise parameter (HNR), five frequency perturbation or jitter parameters (local, local absolute, rap, ppq5, and ddp), and six amplitude perturbation or shimmer parameters (local, local dB, apq3, apq5, apq11, dda) using Praat's cross-correlation algorithm (Table 1; see also Baken & Orlikoff, 2000). The five jitter measures correlated significantly with one another (all  $r > 0.43$ , all  $P < 0.001$ ), and the five shimmer measures correlated significantly with one another (all  $r > 0.88$ , all  $P < 0.001$ ). Hence, using principal component analyses, we reduced each set of measures to a single dimension (henceforth termed Jitter and Shimmer) for which 78% and 94% of the variance was explained, respectively.

## **Body Size and Shape Measurement**

We assessed a total of eight body size and shape measures including height, weight, body-mass-index (BMI), hip-circumference, waist-circumference, chest-circumference, waist-to-hip ratio (WHR), and chest-to-hip ratio (CHR) (see Table 1). Height was measured using a stadiometer or metric tape affixed to the wall and weight was measured using an electronic scale. Participant's BMI was computed as  $\text{weight (kg)} / \text{height (m)}^2$  (where 18.5 to 24.9 indicates normal weight as defined by the World Health Organization). Circumference measures were taken using metric tape following previous work, i.e., waist-circumference was taken at the narrowest point between the rib cage and iliac crest, hip-circumference was taken at the widest point between the waist and thigh, and chest circumference was taken at the widest point with the tape measure placed under the arm pits and, for women, above

209 the breasts (Evans et al., 2006; Hughes, Dispenza, & Gallup, 2004; Singh, 1993; Vukovic et al., 2010).  
210 Participant's WHRs were computed as the ratio of the waist circumference to the hip circumference  
211 and CHRs were computed as the ratio of the chest circumference to the hip circumference.

212 Table 1. Means and standard deviations ( $M \pm sd$ ) of individual vocal parameters and individual indices  
213 of body size or shape.

	Men	Women
Voice Parameters ( $M \pm sd$ )		
$F0$ mean (Hz)	$114.16 \pm 17.01$	$210.52 \pm 21.58$
$F0$ min (Hz)	$90.03 \pm 17.78$	$162.76 \pm 40.20$
$F0$ max (Hz)	$179.19 \pm 65.14$	$370.67 \pm 146.33$
$F0$ $sd$ (Hz)	$14.85 \pm 11.16$	$33.53 \pm 24.19$
$F1$ (Hz)	$466.61 \pm 45.92$	$516 \pm 79$
$F2$ (Hz)	$1520.45 \pm 140.33$	$1848 \pm 200$
$F3$ (Hz)	$2592.49 \pm 132.29$	$3020 \pm 199$
$F4$ (Hz)	$3493.87 \pm 187.54$	$4100 \pm 217$
$F_n$ (Hz)	$2015.99 \pm 93.32$	$2293.55 \pm 247.80$
$Df$ (Hz)	$1008.84 \pm 62.40$	$1194.79 \pm 69.34$
$Pf$ (Z(Hz))	$-0.58 \pm 0.63$	$0.30 \pm 0.47$
$\Delta F$ (Hz)	$1010.66 \pm 46.09$	$1187.16 \pm 66.21$
VTL( $F_i$ ) (cm)	$18.75 \pm 2.10$	$15.61 \pm 1.63$
VTL( $\Delta F$ ) (cm)	$17.35 \pm 0.79$	$14.79 \pm 0.84$
MFF (Hz)	$1589.07 \pm 71.37$	$1847.59 \pm 133.57$
Jitter local (%)	$0.0958 \pm 0.037$	$0.0911 \pm 0.05$
Jitter local absolute (s)	$0.00013 \pm 0.00007$	$0.00006 \pm 0.00003$
Jitter rap (%)	$0.0066 \pm 0.004$	$0.0072 \pm 0.004$
Jitter ppq5 (%)	$0.0067 \pm 0.004$	$0.0070 \pm 0.004$
Jitter ddp (%)	$0.0199 \pm 0.011$	$0.2146 \pm 0.013$
Shimmer local (%)	$0.0958 \pm 0.037$	$0.0911 \pm 0.054$
Shimmer local (dB)	$0.9438 \pm 0.315$	$0.8690 \pm 0.454$
Shimmer apq3 (%)	$0.0416 \pm 0.018$	$0.0425 \pm 0.026$
Shimmer apq5 (%)	$0.0587 \pm 0.028$	$0.0615 \pm 0.044$
Shimmer apq11(%)	$0.0868 \pm 0.039$	$0.0920 \pm 0.076$
Shimmer dda (%)	$0.1249 \pm 0.055$	$0.1285 \pm 0.076$
HNR (dB)	$14.15 \pm 3.21$	$14.73 \pm 4.62$
Body Measure ( $M \pm sd$ )		
Height (cm)	$179.34 \pm 7.16$	$166.37 \pm 6.93$
Weight (kg)	$74.96 \pm 12.44$	$63.28 \pm 10.77$
BMI	$23.27 \pm 3.26$	$22.87 \pm 3.64$
hip circ. (cm)	$99.55 \pm 7.87$	$99.20 \pm 7.69$
waist circ. (cm)	$83.81 \pm 8.12$	$74.54 \pm 7.97$
chest circ. (cm)	$95.87 \pm 8.57$	$88.67 \pm 7.34$
WHR	$0.84 \pm 0.06$	$0.75 \pm 0.05$
CHR	$0.96 \pm 0.07$	$0.90 \pm 0.05$

Abbreviations:  $F_0$  = fundamental frequency;  $F_1$ - $F_4$  = first to fourth formant;  $F_n$  = average formant frequency; MFF = geometric mean formant frequency;  $D_f$  = formant dispersion;  $P_f$  = formant position;  $\Delta F$  = formant spacing;  $VTL(F_i)$  = apparent vocal-tract length derived from mean formants;  $VTL(\Delta F)$  = apparent vocal-tract length derived from formant spacing; HNR = harmonics-to-noise-ratio; BMI = body-mass-index; WHR = waist-to-hip ratio; CHR = chest-to-hip ratio; circ. = circumference.

a. See Baken & Orlikoff (2000) for detailed description and comparison of different jitter and shimmer measures.

## 220 **Statistical Analysis**

221       Shapiro-Wilk tests of normality indicated that many individual voice or body parameters were  
222 non-normally distributed. Hence, we examined relationships between the 19 individual voice  
223 parameters and 8 individual body size or shape parameters using non-parametric Spearman rank  
224 correlations ( $r_s$ ). We then tested whether the strength of various voice-body relationships differed  
225 significantly for samples of men and women by transforming correlation coefficients using Fisher's  $r$ -  
226 to- $z$  transformations and running a series of independent-samples inference tests (Myers & Sirois,  
227 2006). As our goal was to examine predictive utility differences in the strength of relationships between  
228 sexes, we used the more conservative approach of comparing absolute  $r_s$  values (i.e., ignoring the sign  
229 of the correlation, which in some cases would have inflated the apparent sex difference). Effect sizes  
230 for sex differences in  $|r_s|$  are given as Cohen's  $q$  (Cohen, 1988). All analyses were conducted for each  
231 sex separately and all statistical tests were two-tailed with an alpha of .05.

## 232 **Results**

### 233 **Relationships Between Individual Voice and Body Parameters**

234       Correlations between individual voice parameters and indices of body size and shape are  
235 reported in Table 2.

239 Abbreviations:  $F0$  = fundamental frequency;  $F1-F4$  = first to fourth formant;  $F_n$  = average formant frequency; MFF = geometric mean formant frequency;  $Df$  = formant  
240 dispersion;  $Pf$  = formant position;  $\Delta F$  = formant spacing;  $VTL(F_i)$  = apparent vocal-tract length derived from mean formants;  $VTL(\Delta F)$  = apparent vocal-tract length  
241 derived from formant spacing; CFA = confirmatory factor analysis (factor scores); HNR = harmonics-to-noise-ratio; BMI = body-mass-index; WHR = waist-to-hip  
242 ratio; CHR = chest-to-hip ratio; circ. = circumference.  
243 Statistical significance of bivariate Spearman's  $\rho$  correlations ( $r_s$ ) is based on a two-tailed  $t$  test, where \*\*  $P < 0.01$ , \*  $P < 0.05$ , †  $P < 0.10$ . Significant correlations  
244 ( $P < 0.05$ ) are bolded.  
245a. Sample sizes for women's HNRs were 185, and for women's CFA scores were 326 (height), 324 (weight, BMI), and 100 (circumference measures, WHR, CHR).

### **Vocal tract length estimates.**

Compared to all other voice parameters, VTL estimates most strongly predicted height and weight within each sex, explaining upwards of 7.3% and 6.7% of the variance in men's heights and weights, respectively, and 6.7% and 6.3% of the variance in women's heights and weights, respectively. The VTL estimates correlated with men's and women's heights and weights more strongly than did mean  $F_0$  (barring  $F_1$  and  $F_2$ ) replicating the findings of Pisanski et al. (2014a). Although several VTL estimates correlated significantly with men's and women's BMIs, these relationships were weaker than for height or weight.

Among women, most VTL estimates also correlated significantly with women's hip-, chest- and waist-circumferences. The VTL estimates were also good predictor's of women's WHRs, wherein  $F_n$  explained 9% of the variance in WHRs among women. Despite our large sample size ( $n=297$ ), power analysis ( $\alpha=.05$ ,  $\text{power}=.80$ ) indicated that a sample size of only 85 is required for  $F_n$  to reliably predict women's WHRs. Among the VTL estimates, only  $F_n$  correlated significantly with women's CHRs, but explained a mere 1.4% of the variance. Compared to women, VTL estimates were relatively poor predictors of men's body shapes. Only  $F_1$ ,  $F_3$ ,  $P_f$ , or MFF correlated significantly with men's hip- and chest-circumferences, only  $P_f$  and CFA correlated with men's WHRs, and no VTL estimate correlated with men's waist circumferences or CHRs.

### **Fundamental frequency parameters.**

Mean  $F_0$ , while explaining some variance in height within each sex (2.6% among men and 1.9% among women) and in women's weights, BMIs, and circumference measures (up to 4%), did not significantly indicate WHR or CHR in either sex. Rather,  $F_0$  range and variability were better predictor's of body shape than was mean  $F_0$ . Among these  $F_0$  parameters, minimum and maximum  $F_0$  significantly predicted men's and women's CHRs, respectively, and maximum  $F_0$  and  $F_0$  *sd* predicted

269 women's WHRs. Maximum  $F_0$  and  $F_0$  *sd* also correlated significantly with circumference measures in  
270 each sex. Compared to mean  $F_0$ , which did not indicate body shape among men, maximum  $F_0$  and  $F_0$   
271 *sd* explained a noteworthy 11% of the variance in men's hip circumferences.

## 272 **Vocal perturbation and noise parameters.**

273 Shimmer, jitter, and HNR did not correlate with height, weight, or BMI in either sex, with the  
274 exception of HNR that explained a significant but small (1.2%) amount of the variance in women's  
275 heights. However, each of these parameters significantly predicted one or more indices of body shape  
276 including circumference measures, WHRs and CHRs. Compared to all other voice parameters,  
277 shimmer explained the most variance in men's CHRs (5.7%), followed by HNR (4.4%), whereas HNR  
278 explained the most variance in women's WHRs (10.8%), followed by  $F_n$  (9%),  $VTL(F_i)$ , jitter and  
279 shimmer (each 7.3%).

## 280 **Sex differences.**

281 Following Fisher's  $r$ -to- $z$  transformations controlling for sample size, we tested whether the 19  
282 individual voice parameters reported in Table 1 indicated body size or shape significantly better in one  
283 sex than the other. Our results indicated that HNR and  $VTL(F_i)$  predicted women's WHRs better than  
284 men's, and the VTL estimates  $F_4$  and  $D_f$  predicted women's hip circumferences better than men's. In  
285 contrast, maximum  $F_0$ , shimmer and jitter each predicted men's hip circumferences better than  
286 women's (see Table 3). Several trends were observed that did not reach statistical significance, namely:  
287 VTL estimates generally explained more variance in men's than women's heights; noise and  
288 perturbation parameters explained more variance in men's than women's CHRs; and mean  $F_0$   
289 explained more variance in women's than men's weights, BMIs, and circumference measures.

290 Table 3. Significant sex differences in relationships between the voice and body shape

Body shape parameter	Voice measure	<i>z</i>	<i>p</i>	<i>q</i>
Stronger relationships in men:				
Hip circumference	Shimmer	2.84	<.01	.33
	Jitter	2.85	<.01	.33
	<i>F0</i> max	2.16	.03	.25
Stronger relationships in women:

## General Discussion

Our findings demonstrate that the human voice can indicate both body size and shape among adult men and women. We extend the findings of a recent meta-analysis (Pisanski et al., 2014a), and show that in addition to formant frequencies, several other voice parameters including minimum and maximum  $F_0$ ,  $F_0$  variability, jitter, shimmer, and HNR may communicate meaningful information about body size or shape. We emphasize, however, that these voice parameters could explain only a small amount of the variation in various indices of human body size and shape controlling for sex and age, and in some cases, the strength of voice-body relationships varied between men and women. Our key findings are discussed in detail below.

### Vocal Tract Length Estimates

Formants are constrained by the length and dimensions of the mammalian vocal tract that in turn is positively related to skull size and height between and within sexes (Fitch, 2000; Fitch & Giedd, 1999). Thus, formants predict vocal tract length in many mammals including humans (Fitch & Hauser, 2003; Taylor & Reby, 2010). In men, formants also appear to predict circulating levels of testosterone (Bruckert et al., 2006; Evans, Neave, Wakelin, & Hamilton, 2008) that can affect muscularity and the distribution of fat on men's bodies (Blouin et al., 2008), but it remains unknown whether sex hormones affect the formant frequencies of women's voices. Our results indicate that formant-based VTL estimates correlate with men's and women's heights and weights more reliably than other voice parameter investigated in this study. In addition, our study shows that VTL estimates correlate with one or more indices of body shape in each sex, including hip-, waist-, and chest-circumferences, WHRs and CHRs.

Formants were particularly robust indicators of body shape among women. One previous study tested but failed to find significant relationships between women's voice parameters (principal

325 components representing  $F0$  and formants) and body shape. This may be because the authors used  
326 factor scores in their regression analyses and a sample of only 30 women (Collins & Missing, 2003).  
327 Thus, our study presents the first evidence that formants can explain variation in women's body shapes  
328 given an adequate sample size (here,  $n=297$ , but power analysis suggested that a sample of  $n=85$  would  
329 suffice). Moreover, many individual VTL estimates explained several times more variance in women's  
330 than men's circumference measures and WHRs. Indeed, only four formant measures ( $F1$ ,  $F3$ ,  $Pf$  and  
331 MFF) significantly predicted variation in men's hip-circumferences and chest-circumferences, and one  
332 (CFA) predicted variation in men's WHRs, whereas no voice parameter predicted men's waist-  
333 circumferences. Theoretically, the finding that women's voices may carry information about their  
334 WHRs is in line with a growing body of literature implicating the 'hour-glass' shape of a woman's  
335 body as a key indicator of her age, fertility status, and health (Pisanski & Feinberg, 2013; Singh &  
336 Singh, 2011). As an important determinant of her physical attractiveness and desirability as a potential  
337 mate, a woman's body shape may be advertised through various modalities, including her voice.  
338 However, on a proximate level, the mechanism linking formants to women's WHRs remains unclear  
339 and will require a more comprehensive understanding of the relative roles of androgens and estrogens  
340 on formant production (particularly among women) and on regional fat distribution.

#### 341 **Fundamental Frequency Parameters**

342 Previous studies have shown that when sex and age are controlled, mean fundamental  
343 frequency ( $F0$  or voice pitch) is a weak predictor of height in humans (Pisanski et al., 2014a) and of  
344 body size in many other mammals (for reviews, see Ey et al., 2007; Fitch & Hauser, 2003). The mass  
345 and tension of the vocal folds determine mean  $F0$  (Titze, 1994). However, human vocal folds can  
346 develop and grow independently of the rest of the body, as their mass appears more closely related to  
347 testosterone levels at puberty and into adulthood than to body size (Dabbs & Mallinger, 1999; Harries,  
348 Walker, Williams, Hawkins, & Hughes, 1997).

349 In our study, mean *F0* predicted weight, BMI and body circumferences only among women,  
350 and did not predict WHR or CHR in either sex. Our results suggest that while mean *F0* may indicate  
351 women's body masses, it is a relatively poor predictor of body shape in either sex, generally supporting  
352 the results of past work (Bruckert et al., 2006; Collins, 2000; but see controlling for age: Evans et al.,  
353 2006). Also in line with our results are those of a meta-analysis that showed a negative relationship  
354 between mean *F0* and weight among women but not men (Pisanski et al. 2014a). One other study  
355 reported a significant negative correlation between women's mean *F0* and factor scores derived from a  
356 principal component that included women's weights, BMIs, percentage body fat, waist- and hip-  
357 circumferences, and WHRs (Vukovic et al., 2010), however it is difficult to ascertain whether this  
358 relationship was driven by body mass, body shape, or both. One possible explanation for the apparent  
359 negative relationship between women's mean *F0* and body mass is that relatively higher levels of  
360 androgens and/or lower levels of estrogens may cause some women to develop both more masculine  
361 voices (larger vocal folds and lower *F0*, Abitol et al., 1999; Titze, 1994) as well as more masculine  
362 bodies (heavier and more muscular, Björntorp, 1991; Blouin et al., 2008). The lack of a relationship  
363 between mean *F0* and body mass in men suggests that the ratio of estrogens to androgens may play a  
364 key role in driving this relationship.

365 Although research in other animals indicates that a variety of voice features produced by the  
366 vocal source (i.e., the larynx and vocal folds for terrestrial mammals) play a role in acoustic  
367 communication (see, e.g., Reby & McComb, 2003; Tyack & Miller, 2002), most human studies  
368 examining the indexical functions of voice have focused on mean *F0* (for reviews, see Feinberg, 2008;  
369 Puts, Jones, & DeBruine, 2012b). Our results indicate that *F0* range and variability are generally better  
370 predictors of body shape than is mean *F0*. In particular, minimum *F0* explained several times more  
371 variation in men's CHRs, and maximum *F0* in men's circumference measures, than did mean *F0*.  
372 Indeed, physical height and the girth of the chest relative to the lower body are key predictor's of  
373 men's, but not women's, physical attractiveness (Pawlowski et al., 2000; Swami et al., 2007).

374 Similar to Puts et al. (2012), whose study samples included men from the northeastern US and  
375 Tanzania, we found that *F0* variability was unrelated to height among men (and women) from three  
376 additional cultures. However, our results indicated that *F0 sd* explained 10% of the variance in men's  
377 hip-circumferences and correlated negatively with women's weight's, BMIs, circumferences measures  
378 and WHRs. Thus, in our study, low *F0* variability indicated larger body circumferences in both sexes  
379 and more masculine (lower) WHRs among women. Other recent work investigating *F0* variability in  
380 humans suggests that this sexually dimorphic voice parameter may be an important signal of quality.  
381 Low *F0* variability produces a perceptually monotone voice that is more common among men than  
382 women (Puts et al., 2012), is associated with self-reported physical dominance and reproductive  
383 success in men (Hodges-Simeon et al., 2010, 2011), and may also predict circulating levels of  
384 testosterone and physical strength (Puts et al., 2012).

### 385 **Vocal Perturbation and Noise Parameters**

386 To our knowledge, no previous study has investigated relationships between perturbation or  
387 noise parameters and body shape. We found that jitter, shimmer and HNR each indicated one or more  
388 indices of body shape in both men and women. Shimmer and jitter correlated negatively with hip  
389 circumferences among men and with waist- and chest-circumferences among women. Both parameters  
390 explained around 12% of the variance in men's hip-circumferences, significantly more than in  
391 women's hip-circumferences.

392 Among women, shimmer and jitter correlated negatively with WHR (explaining 7% of the  
393 variance) and jitter with CHR, whereas HNR correlated positively with WHR and explained more  
394 variance in women's WHRs (11%) than did any other voice parameter. Thus, women with relatively  
395 low jitter and shimmer (less perturbation) and high HNRs (less noise) had relatively more masculine  
396 body shapes (higher WHRs or CHRs) than did other women. Some researchers have speculated that  
397 relationships between perturbation or noise parameters and body shape may be related to sex hormone

398 levels, particularly among women (Linders et al., 1995; Silverman & Zimmer, 1978; Prelevic, 2013).  
399 As the vocal folds have androgen receptors that are sensitive to an influx in circulating testosterone,  
400 which increases vocal fold mass (Titze, 1994), women with relatively high androgen and/or low  
401 estrogen levels may experience a greater increase in vocal fold mass compared to other women. On the  
402 basis that larger vocal folds may oscillate with fewer irregularities than smaller vocal folds (Linders et  
403 al., 1995), jitter and shimmer may be lower, and HNR higher, among women with more masculine  
404 hormonal profiles and more masculine body shapes. Our results support this prediction for women, but  
405 not men, among whom shimmer correlated positively, and HNR negatively, with CHR. The possible  
406 mechanism linking voice perturbation and noise parameters to men's body shapes is unclear.

407 Our results further indicate that although perturbation and noise parameters predicted body  
408 shape, these parameters could not reliably predict height, weight, or BMI in either sex. Previous work  
409 has also generally failed to find robust relationships between these parameters and adult height  
410 (González, 2007; Hamdan et al., 2012; but see in children: Linders et al., 1995), however two studies  
411 reported significant positive relationships between jitter or shimmer and certain indices of body mass  
412 including body surface area, trunk fat, or muscle mass (González, 2007; Hamdan et al., 2012). As the  
413 results of studies to date are mixed, additional studies are needed to determine whether relatively taller  
414 or heavier adults show more irregularities in the pitch and amplitude of their voices than do others.

## 415 **Limitations and Future Directions**

416 Our voices and bodies change throughout the lifespan, but the most drastic changes occur at  
417 puberty and after the age of about 50 (Abitol et al., 1999; Hollien, Green & Massey, 1994). Hence, in  
418 the present study, we focused our analyses on adults aged 17-30 years to reduce possible age effects on  
419 voice-body relationships. Age data were unavailable for one sample (Scotland), however the sample  
420 was comprised of University students whose ages likely fell within this range. To test whether the  
421 strength of voice-body relationships changes across the lifespan, future work should include samples

422 with a wider age range, including pre-pubescent children. Moreover, although our study included three  
423 large and independent samples of adults from Canada, Scotland and Germany, future replications of  
424 this work would also benefit from including multiple other cross-cultural samples, particularly from  
425 less industrialized regions of the world.

426         The voice-body relationships reported in this exploratory study warrant replication, particularly  
427 those between perturbation or noise parameters and body shape. Reliable measurement of jitter and  
428 shimmer is inherently difficult, particularly with voices in which these parameters are high, as their  
429 measurement requires accurate identification of cycle boundaries and may also vary as a function of  
430 recording hardware, acoustic analysis software, and verbal content (Buder, 2000; Maryn et al., 2009).  
431 These parameters can also be difficult to detect and discriminate acoustically (Hillenbrand, 1987;  
432 Kreiman & Gerratt, 2005). The average values of jitter, shimmer, and HNR in our samples fell within a  
433 non-pathological normal range. However, the mechanisms potentially linking these parameters to body  
434 size or shape remain unclear. In our study we have speculated about possible hormonal mechanisms  
435 linking variation in the human voice to variation in body size and shape, but we did not measure  
436 hormone levels in this study. Future studies may focus on further identifying the hormonal mechanisms  
437 of voice production in humans and elucidating the proximate causes of the relationships and sex  
438 differences in vocal cues to body size and shape reported here.

439         Unfortunately we cannot infer from our data whether sex differences in vocal cues to body size  
440 and shape are the product of sexual selection. It is equally likely, for instance, that men have been  
441 selected to exaggerate their body size by lowering the frequencies of their voices (Fitch & Giedd, 1999;  
442 Fitch & Reby, 2001; Morton, 1977), and may modulate their formants more than women in ways that  
443 reduce the degree to which formants honestly indicate body mass and shape, which are more malleable  
444 and variable than is height. At a proximate level, many factors may contribute to sex differences in  
445 vocal cues to body size and shape. The vocal tract and resultant formants are sexually dimorphic (Fitch

446 & Giedd, 1999; Titze, 1989). There are also marked sex differences in steroid hormone concentrations  
447 and in their effect on vocal anatomy (Abitbol et al., 1999; Lieberman et al., 2001) and on fat  
448 distribution (Blouin et al., 2008; Singh, 1993). All or any of these factors may affect the relative degree  
449 to which vocal parameters predict variation in body size and shape within and between sexes.

450 Intimately tied to the question of whether reliable indicators of body size and shape are present  
451 in the voice is whether listeners are able to accurately gauge size and shape from the voice and, if so,  
452 which vocal parameters listeners use to do so. Perceptual studies of voice have generally focused on  
453 listener's assessments of height and weight (Bruckert et al., 2006; Collins, 2000; Gonzalez, 2006;  
454 Krauss, Freyberg, & Morsella, 2002; Pisanski et al., 2014b; Rendall et al., 2007; Smith & Patterson,  
455 2005). Although accuracy in these tasks is generally low, these studies indicate that listeners can gauge  
456 height and weight from the voice above chance, and that accuracy is highest (about 60%) in two-  
457 alternative forced choice paradigms. Compared to height and weight, relatively few studies have  
458 examined assessment of body shape from the voice. Hughes, Harrison and Gallup (2009) found that  
459 listeners were able to gauge women's WHRs (but not shoulder-to-hip ratios, SHRs), and men's SHRs  
460 (but not WHRs) from the voice alone. Future studies may test whether the sex of the listener affects the  
461 accuracy of body shape assessments, as there is some evidence that men are better than women in  
462 voice-based assessments of height (Charlton et al., 2013; but see also Rendall et al., 2007). Moreover,  
463 while it is clear that listeners utilize both *F0* and formant information to gauge height (Charlton et al.,  
464 2013; Rendall et al., 2007; Pisanski et al, 2014b), it remains unknown whether listeners use jitter,  
465 shimmer or HNR to gauge either body size or shape from the voice. Evidence that listeners are  
466 generally insensitive to perturbation parameters in the normal range of variation (Kreiman & Gerratt,  
467 2005) suggests that this is unlikely.

## 468 **Conclusions**

469           We examined relationships among a wide array of voice parameters and indices of both body  
470 size and shape in a large cross-cultural sample of men and women. In response to our research  
471 questions outlined in the Introduction, our results revealed that: (1) Formants predict height and weight  
472 in both men and women better than does any other voice parameter, including mean *F0* and non-mean-  
473 based *F0* parameters (*F0* range and variability); (2) Various *F0*, formant, noise and perturbation  
474 parameters predicted body shape among men or women. Notably, *F0* range and variability were better  
475 predictors of body shape than was mean *F0* in both sexes, formants could explain a similar amount of  
476 variance in women's body shapes as in women's body sizes, and jitter, shimmer and HNR were  
477 particularly good predictors of body shape including women's WHRs and men's CHRs; (3) Various  
478 VTL estimates predicted women's WHRs and hip circumferences significantly better than men's, but  
479 shimmer, jitter and maximum *F0* predicted men's hip circumferences better than women's. By  
480 informing and guiding future research investigating the mechanisms and functions of vocal  
481 communication in humans, these findings may provide further insight into how the human voice and  
482 body have been shaped by sexual selection (Puts et al., 2012b), and may offer practical applications for  
483 estimating the body size of vocalizers in criminal profiling and remote medical monitoring of obese or  
484 malnourished patients.
